Male Sprague-Dawley rats were fed diets enriched in n-6 or n-3 polyunsaturated fatty acids. Half of the animals were fed a cholesterol-containing diet for 2 weeks before sacrifice. 5-Hydroxy-6,8,11,14-eicosatetraenoic acid (5-HETE) accumulated in the livers of rats fed the cholesterol-containing diet, as well as in the livers of animals fed a high-cholesterol diet. The concentration of 5-HETE increased with both dietary cholesterol and arachidonic acid in the diet. 5-HETE was present as a free radical metabolite that was conjugated to glutathione and a variety of albumin variants. It is known that lipid peroxides are formed from 5-HETE. Consequently, the formation of 5-HETE was quantified and the levels of malondialdehyde (MDA) and 3-hydroxy-9-oxononanoic acid (HODE), two of the major peroxidation products of this oxidation product, were determined. The two diets fed to the animals produced large increases in the formation of 5-HETE and, subsequently, MDA. Feeding the cholesterol-containing diet induced an increase in the formation of HODE, but this effect was minimal in animals fed the high cholesterol diet. The free radical scavengers Na-t-butyl-phosphate (TBP) or dimethyl sulfoxide (DMSO) reduced the formation of 5-HETE and MDA, but did not change the formation of HODE. TBP fed to animals fed a high cholesterol diet had no effect on the formation of MDA, but did reduce the formation of HODE. DMSO treatment had the opposite effect, decreasing HODE formation and increasing MDA formation. These results are consistent with the idea that lipid peroxide formation is a dual process. Lipid peroxide formation can be initiated by scavenging of unformed free radicals and not necessarily from the oxidation of readily formed free radicals.Luteinizing hormone (LH
